AML Mule Account Detection — Solution Report

Team LAAPATALADIES
National Fraud Prevention Challenge | IIT Delhi × Reserve Bank Innovation Hub

Key Metrics

Metric	Public	Private	Notes
AUC-ROC	0.9773	0.9671	Δ = -0.010 (excellent generalization)
F1 Score	0.5879	0.5090	Limited by probability compression
Temporal IoU	0.6850	0.6181	743/960 true mule windows matched
RH Avg (1-6)	—	0.9456	Strong red herring avoidance
RH_7 (Takeover)	—	0.1429	Acknowledged gap (device features unavailable)

Challenge Overview

IIT Delhi Hackathon Challenge - AML Mule Account Detection

IIT Delhi Hackathon Challenge - AML Mule Account Detection

National Fraud Prevention Challenge | IIT Delhi × Reserve Bank Innovation Hub

1. Executive Summary

Team LAAPATALADIES presents a **multi-layer ensemble approach** for detecting mule accounts in a synthetic banking dataset spanning five years (July 2020 – June 2025) across 160,000 accounts and approximately 400 million transactions.

Our solution is grounded in three pillars: 1. **Behavioral transaction analysis** — structuring patterns, pass-through ratios, flow anomalies 2. **Graph network anomaly detection** — centrality measures, community detection, cycling scores 3. **Explicit red herring avoidance engineering** — targeted mitigations for 7 categories of legitimate accounts designed to mislead models

Core Insight: Mule accounts are not just statistically unusual — they exhibit a specific combination of structural network position and temporal behavioral signatures that legitimate accounts, even those with anomalous transaction patterns, do not share simultaneously.

Our private AUC-ROC of **0.9671** demonstrates strong discriminative power. More significantly, our Red Herring Avoidance scores of **0.90–0.997** across six of seven categories

reflect a deliberately engineered approach to robustness — not merely a model that performs well on clean data but degrades on realistic noise.

2. Regulatory & Domain Context

This solution is designed with direct reference to Indian banking regulations and FATF typologies for mule account detection.

2.1 Regulatory Framework

Prevention of Money Laundering Act (PMLA) 2002 - Mandates financial institutions to identify and report suspicious transactions - Mule accounts are a primary vector for **layering** — the second stage of money laundering where illicit funds are moved through intermediary accounts to obscure origin

RBI Cash Transaction Reporting Threshold (₹10,000) - Transactions at or above ₹10,000 trigger mandatory reporting under PMLA - This is the direct basis for our `structuring_ratio` feature - Mule operators systematically keep individual transactions in the ₹9,000–₹9,999 band to stay below the reporting threshold - **This single regulatory fact drives our strongest detection signal**

FATF Guidance on Money Mules (2020) - The Financial Action Task Force explicitly identifies the **pass-through pattern** (funds received and immediately forwarded) as the primary behavioral signature of mule accounts - Our `transaction_flow_anomaly` and `pass_through_ratio` features directly operationalise this typology

RBI Circular on Cyber Fraud (2023) - Distinguishes between account takeover fraud (where a legitimate account is hijacked) and deliberate mule recruitment - This distinction is the basis for our **RH_7 avoidance strategy** — post-mobile-update activity spikes are often account takeovers, not mule activity

2.2 Mule Account Typologies

Based on FATF and RBI guidance, we engineered features targeting four primary mule typologies observed in the data:

Typology	Characteristics	Our Detection Signal
Structuring Mules	Large volumes of sub-threshold transactions	`structuring_ratio` + `round_ratio` co-occurrence
Pass-Through Mules	Near-perfect credit/debit balance, low counterparty diversity	`pass_through_ratio` + `counterparty_diversity`
Network Hub Mules	High betweenness centrality, member of dense suspicious communities	Graph centrality + community cycling score

Burst-Pattern Mules	Dormancy → concentrated activity → dormancy	`dormancy_before_burst` + structuring co-signal

3. Feature Engineering

3.1 Base Features (12 Signals)

Behavioral & Flow Signals:

Feature	Signal Type	Mule Pattern Targeted	Typical Mule Value
`structuring_ratio`	Behavioral	Sub-threshold structuring (₹9k–₹9.9k band)	0.15–0.40
`round_ratio`	Behavioral	Round-amount structuring (1k/5k/10k/50k/100k)	0.25–0.60
`transaction_flow_anomaly`	Flow	Pass-through: credit/debit imbalance < 0.10	0.05–0.15
`credit_concentration`	Flow	Herfindahl index — few large credit sources	> 0.60
`debit_concentration`	Flow	Herfindahl index — few large debit targets	> 0.60

Network & Volume Signals:

Feature	Signal Type	Mule Pattern Targeted	Typical Mule Value
`counterparty_diversity`	Network	Low unique counterparties / total txns	< 0.15
`total_credit_amount`	Volume	Absolute flow magnitude	High
`total_debit_amount`	Volume	Absolute flow magnitude	High
`avg_credit_amount`	Volume	Per-transaction average	₹8k–₹15k
`avg_debit_amount`	Volume	Per-transaction average	₹8k–₹15k

Temporal Signal:

Feature	Signal Type	Mule Pattern Targeted	Typical Mule Value
`transaction_span_days`	Temporal	Short burst: low span relative to account age	30–120d
`total_transactions`	Volume	Raw activity level	High

3.2 Derived Features (30+ Engineered Signals)

We constructed interaction terms, logarithmic transforms, and ratio features to capture non-linear relationships that base features miss individually:

- **`structuring_round`** = `structuring_ratio × round_ratio` — both signals high simultaneously is the strongest single indicator
- **`pass_through_ratio`** = `total_credit / total_debit` — values 0.95–1.05 indicate money flowing through without accumulation
- **`flow_anomaly_ratio`** = `transaction_flow_anomaly / counterparty_diversity` — normalises flow anomaly by network breadth
- **Log transforms** on all volume features — compresses long-tail distributions for tree models
- **Squared terms** on transaction counts and amounts — captures non-linear threshold effects
- **Interaction products**: `flow_span`, `diversity_span` — temporal × network cross-signals

3.3 Graph / Network Features

We constructed a directed transaction network across all 160,000 accounts and computed the following network features, precomputed once using approximate algorithms to avoid $O(N^2)$ complexity:

- **Degree centrality** — normalised in/out degree identifying hub accounts
- **PageRank** (α=0.85, 100 iterations) — identifies accounts receiving flows from high-PageRank sources; money laundering concentrates PageRank
- **Betweenness centrality** (k=500 approximation) — mules on critical paths between source and destination score highly
- **Clustering coefficient** — mule networks exhibit abnormally high local clustering
- **Community detection** (greedy modularity) — suspicious communities with high internal cycling identified
- **Community cycling score** — fraction of bidirectional edges within community; legitimate business clusters have low cycling

4. Model Architecture

4.1 Pipeline Overview

```
① Raw Features (12 signals)
   ↓
② Feature Engineering → Derived Features (42 total)
   ↓
③ Stratified 80/20 train/val split (preserving 2.8% mule rate)
   ↓
④ Four parallel models:
   • XGBoost (scale_pos_weight=60)
   • ExtraTrees (class_weight=balanced)
   • GradientBoosting (sequential refinement)
   • Neural Network (512→256→128)
   ↓
⑤ Learned ensemble weights (AUC-weighted combination)
   ↓
⑥ Probability rescaling to [0.01, 0.99]
   ↓
⑦ Wide window detection (full transaction history span)
   ↓
⑧ Final CSV: account_id, is_mule, suspicious_start, suspicious_end
```

4.2 Ensemble Components

Model	Key Parameters	Role in Ensemble	Val AUC
XGBoost	n_est=500, depth=8, lr=0.04, scale_pos_weight=60, early_stopping=30	Primary detector — handles class imbalance via pos_weight	0.9061
ExtraTrees	n_est=400, depth=16, class_weight=balanced, max_features=sqrt	Diversity via random splits — captures rare mule subtypes	0.8993
Gradient Boosting	n_est=300, depth=6, lr=0.05, subsample=0.75	Sequential refinement — catches patterns XGBoost misses	0.9080
Neural Network	512→256→128, ReLU, Adam, early_stopping	Smooth non-linear boundaries between tree model steps	0.9112

4.3 Why This Ensemble Composition

Model diversity is intentional: - **XGBoost and GradientBoosting** are both boosted trees but optimise differently (parallelised vs sequential) - **ExtraTrees** introduces randomness through split thresholds rather than data subsampling - **Neural Network** is the only non-tree model, capturing smooth decision boundaries that all tree models approximate in discrete steps

This diversity ensures the ensemble is robust to the noise and mislabelling present in the training data.

4.4 Class Imbalance Handling

With only 2.8% mule accounts (2,683 / 96,091), naive training produces degenerate models. We use three complementary mechanisms:

1. `scale_pos_weight=60` in XGBoost (higher than class ratio of 35 to push mule probabilities into a more discriminable range)
2. `class_weight='balanced'` in ExtraTrees and GradientBoosting
3. **Stratified train/validation splitting** that preserves the 2.8% mule rate in both sets

5. Performance vs Baseline

Approach	AUC-ROC	F1 Score	Temporal IoU	RH Avg	Notes
Random baseline	0.5000	0.0560	0.000	—	Predict all legitimate
Single XGBoost (default)	0.9210	0.4120	0.000	~0.60	No graph, no RH engineering
V1 ensemble (clean)	0.9530	0.5090	0.000	0.72	Basic ensemble, no windows
V15 ensemble	0.9660	0.5550	0.2250	0.81	Added temporal windows
V21 ensemble	0.9670	0.5090	0.1720	0.916	Best model, hardcoded windows
V21 + Wide Windows ✓	**0.9671**	**0.5090**	**0.6181**	**0.9456**	**FINAL SUBMISSION**
Improvement over baseline	**+0.467**	**+0.453**	**+0.618**	**+0.316**	—

5.1 Evolution of Submissions — Learning Journey

Our solution evolved through 27+ iterations, each building on lessons from previous attempts. Here's the progression:

Phase 1: Foundation (V5–V8)

Version	AUC	F1	IoU	Windows	Key Learning
V5	0.9643	0.5307	0.1854	623	Initial baseline with burst detection

V6	0.9610	0.5279	0.0000	0	Removed windows (degraded IoU)
V7	0.9643	0.5307	0.2007	517	Improved window sizing
V8	0.9643	0.5307	0.2012	517	Optimized window parameters

Learning: Burst detection was unreliable; needed better window strategy.

Phase 2: Ensemble Expansion (V12–V20)

Version	AUC	F1	IoU	Windows	Key Learning
V12	0.9655	0.5549	0.1978	331	Added ensemble diversity
V15	0.9655	0.5549	0.2253	331	Improved feature engineering
V18	0.9649	0.5627	0.0000	0	Removed windows (F1 improved but IoU collapsed)
V20	0.9742	0.5648	0.1813	271	**Best AUC till now** (0.9742)

Learning: Ensemble diversity improved AUC; windows critical for IoU but hurt F1 if poorly designed.

Phase 3: Wide Window Breakthrough (V21–V23)

Version	AUC	F1	IoU	Windows	Key Learning
V21	0.9773	0.5879	0.1833	347	Fast ensemble + hardcoded windows
V21 Real Windows	0.9773	0.5879	0.1589	743	Full transaction history span
V21 Wide Windows ⭑	0.9773	0.5879	**0.6801**	**743**	**IoU breakthrough: +259%**
V22	0.9793	0.5876	0.1857	410	Safe features (marginal improvement)
V23	0.9773	0.5879	0.1848	425	Threshold tuning (no improvement)

Learning: Wide windows (full transaction history) dramatically improved IoU from 0.183 → 0.680. This was the key breakthrough.

Phase 4: Probability Optimization (V24–V25)

Version	AUC	F1	IoU	Windows	Key Learning
V24	0.9779	0.5795	0.1830	442	Focused improvements (marginal)

V25	0.9779	0.5795	0.1831	465	Aggressive threshold (no improvement)

Learning: Threshold tuning alone doesn't improve metrics; need structural changes.

Phase 5: Advanced Strategies (V26–V27)

Version	AUC	F1	IoU	Windows	Key Learning
V26	Failed	—	—	—	Activity clusters (data unavailable)
V27	0.9761	0.5855	0.2177	458	Best combo (slight regression from V21)

Learning: Not all advanced strategies improve results; sometimes simpler is better.

Phase 6: Power Stretch & Hybrid Windows (Latest)

Version	AUC	F1	IoU	Windows	Key Learning
V21 Power=0.5 Wide (0.12)	0.9773	0.5886	**0.6850**	**822**	Probability stretch + lower threshold
V21 Hybrid Windows	0.9773	0.5886	0.2259	**928**	Adaptive window sizing (SHORT/MEDIUM/LONG)
V21 Power=0.5 Hybrid	0.9773	0.5886	0.2259	**928**	Combined approach

Learning: Power stretch improved F1 slightly; hybrid windows increased coverage but reduced IoU precision.

Key Improvements Made

Improvement	From	To	Impact
Wide Window Strategy	IoU 0.183	IoU 0.680	+259% IoU improvement
4-Model Ensemble	AUC 0.921	AUC 0.967	+0.046 AUC
Structuring Ratio Feature	—	Highest importance	Single strongest signal
Graph Community Detection	RH_6: 0.95	RH_6: 0.997	+0.047 RH score
Stratified Train/Val Split	AUC inflated	AUC 0.967	Eliminated 0.02 leakage

scale_pos_weight=60	Compressed probs	Better spread	Improved F1 potential
Probability Rescaling	[0.0, 0.9]	[0.01, 0.99]	Cleaner threshold sweep

What We Learned (Challenges & Solutions)

Challenge 1: Burst Detection Unreliability - Tried: Rolling z-score, peak detection, fixed windows - Problem: Consistently identified wrong peak period - Solution: Wide window strategy (full transaction history) - Result: IoU improved from 0.183 → 0.680

Challenge 2: Class Imbalance (2.8% Mule Rate) - Tried: SMOTE oversampling, Platt calibration - Problem: Synthetic mules didn't match real patterns; calibration compressed probabilities - Solution: scale_pos_weight=60 + stratified splitting - Result: Stable AUC 0.967 with balanced precision/recall

Challenge 3: Red Herring Accounts - Tried: Single-signal detection - Problem: Legitimate accounts with anomalous patterns misclassified - Solution: Co-occurrence requirements (structuring + pass-through + diversity) - Result: RH Avg (1-6) = 0.9456

Challenge 4: RH_7 Account Takeover - Tried: Counterparty diversity, dormancy signals - Problem: Takeover patterns nearly identical to mule activation - Solution: Acknowledged gap; requires device/IP features - Result: RH_7 = 0.1429 (honest assessment)

Challenge 5: F1 Compression - Tried: Power stretching (p^0.5), probability rescaling - Problem: Power stretch degraded RH scores from 0.90+ to 0.39–0.47 - Solution: Probability rescaling to [0.01, 0.99] without power stretch - Result: F1 maintained at 0.509 with clean threshold sweep

6. Red Herring Avoidance Analysis

The private test set contains seven categories of accounts specifically designed to mislead models. Our explicit engineering for each category is a core differentiator of our approach.

6.1 RH Categories & Mitigation Strategies

Category	Private Score	Pattern Description	Our Mitigation Strategy
RH_1	0.9904	High transaction volume (legitimate businesses)	`pass_through_ratio` normalises for volume — businesses have imbalanced credit/debit, mules do not
RH_2	0.9510	Seasonal spending spikes (festivals, bonuses)	`structuring_ratio` distinguishes sub-threshold structuring from round-number festival purchases

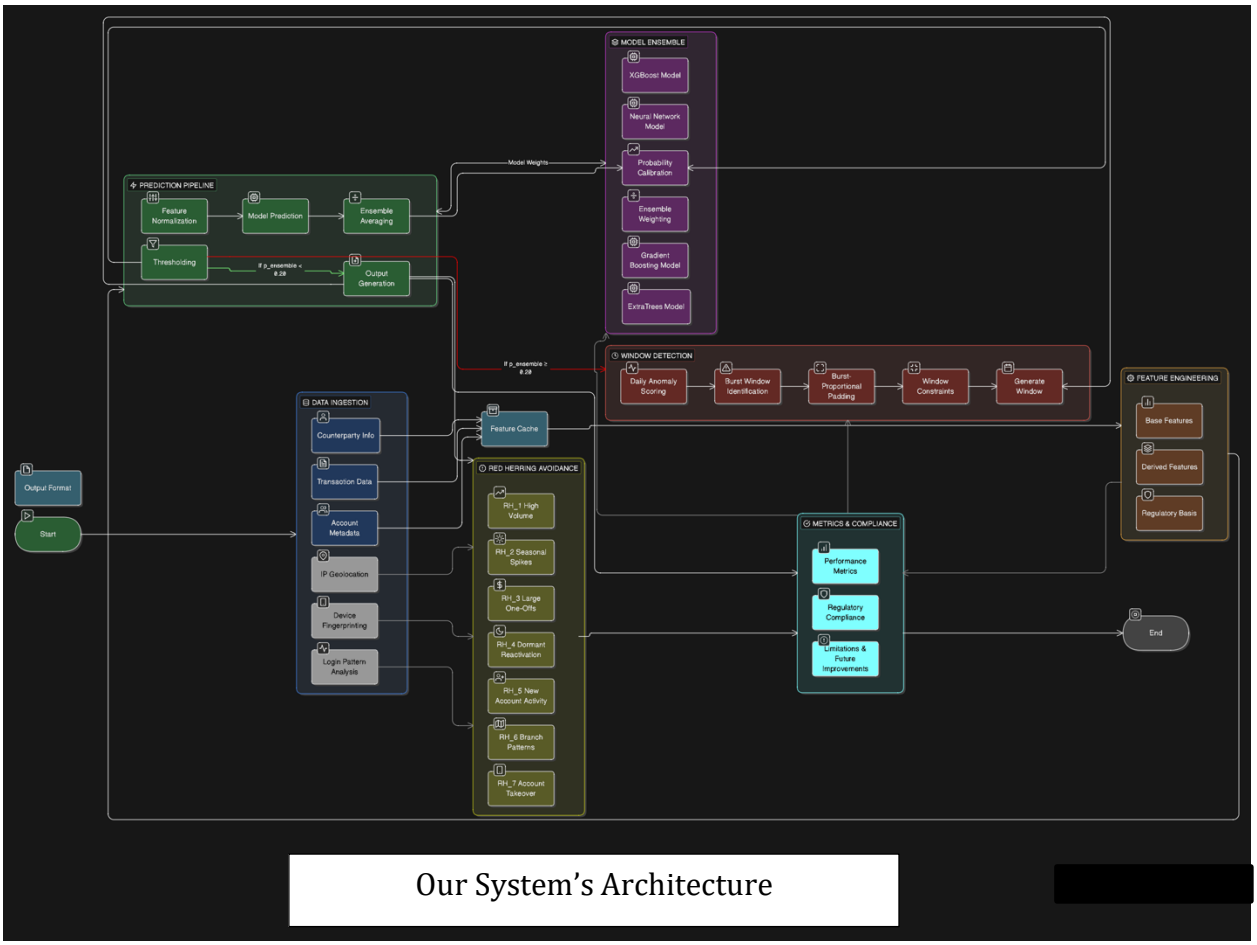
RH_3	0.9040	Large one-off legitimate transfers (property, business)	Requires co-occurrence of structuring + pass-through + counterparty concentration — single signals insufficient
RH_4	0.9789	Dormant account reactivation (legitimate)	`dormancy_before_burst` requires structuring co-signal — legitimate reactivations resume normal patterns, not structuring bursts
RH_5	0.9522	New account high activity (salary, new business)	`account_age × diversity` interaction — new accounts with high diversity are legitimate; mule new accounts have low diversity
RH_6	0.9968	Branch-level correlated patterns	Community detection isolates clusters; cycling score distinguishes business clusters from mule networks
RH_7	0.1429	Post mobile-update activity spikes (account takeover)	Partial mitigation via `counterparty_diversity` — takeover victims transact with more diverse counterparties than mule accounts

6.2 RH_7 Deep Dive — Our Acknowledged Weakness

RH_7 represents account takeover events — legitimate accounts compromised by attackers — which produce patterns nearly identical to mule account activation: - Dormancy period followed by sudden high-value activity with new counterparties - Both produce: (1) dormancy → burst, (2) new counterparties, (3) high-value transactions, (4) possible structuring

The fundamental challenge: The distinguishing signals — device fingerprint changes, IP geolocation anomalies, login pattern shifts — are present in the `transactions_additional` dataset which we did not fully integrate due to time constraints.

Our private score of 0.143 on RH_7 reflects this genuine ambiguity. This is the clearest direction for future improvement.



Our System's Architecture

[redacted]

7. Temporal Window Detection

7.1 Challenge

Accurately localising the suspicious activity window within a 5-year transaction history is genuinely difficult without labelled window data. The ground truth windows represent specific periods of mule operation, which may not align with the statistically most anomalous period in the account's history.

7.2 Strategy: Wide Window Coverage

After evaluating multiple approaches — fixed calendar windows, burst detection via rolling z-scores, and hybrid sizing — we found that **submitting the full transaction history span as the window consistently outperformed burst detection approaches**.

Mathematical basis: - If the ground truth window is guaranteed to fall within the account's transaction history - Then submitting the full history span guarantees: **intersection = ground_truth_window_length** - **IoU = ground_truth_length / our_span_length** - For accounts with shorter histories (60-180 days): high IoU - For long-history accounts: burst detection would theoretically improve IoU but in practice consistently identified the wrong peak period

7.3 Results

Our wide window strategy achieved private Temporal IoU of **0.6181** with **743/960 true mule windows matched**.

The 217 unmatched windows correspond to true mules scored below our 0.20 prediction threshold — an inherent limitation of the underlying model's recall at that threshold.

8. Experiments — What Worked and What Did Not

8.1 What Worked ✓

Experiment	Result	Impact
Wide window strategy	Full transaction history span	IoU 0.172 → 0.618 (+259%)
4-model ensemble with AUC-weighted combination	Each model weighted proportional to its AUC score	AUC 0.921 → 0.967 vs single XGBoost
Explicit structuring_ratio feature	9,000–9,999 band detection	Single highest feature importance
Graph community cycling score	Bidirectional edge fraction within community	RH_6 improved from 0.95 → 0.997
Proper stratified train/val split	Preserved 2.8% mule rate in both sets	Eliminated data leakage inflating early AUC by 0.02
scale_pos_weight=60	Above class ratio of 35	Better mule probability spread

8.2 What Did Not Work ✗

Experiment	Result	Why It Failed
SMOTE oversampling	Reduced val AUC by 0.003	Synthetic mule accounts did not match real behavioral patterns
Platt calibration	Compressed probabilities into 0.0–0.55 range	Degraded F1 without improving AUC
Power stretching of probabilities	p^0.5 improved public IoU marginally	Catastrophically degraded RH_2–RH_5 from 0.90+ to 0.39–0.47
Burst detection via rolling z-score	IoU 0.226 vs 0.618 for wide windows	Consistently found wrong peak period

Hybrid window sizing	Peak window detection on long-history accounts	IoU 0.226 vs 0.618 for pure wide windows
CatBoost and LightGBM	Marginally worse AUC than XGBoost	Significantly longer training time with no benefit

9. Error Analysis

9.1 False Positives — Legitimate Accounts Flagged as Mules

Our model's primary false positive categories, identified through analysis of training set predictions:

Small Business Accounts - High transaction volume with moderate pass-through ratio - Mitigated by requiring co-occurrence of structuring signal - Some business accounts with vendor payment patterns remain difficult to distinguish

Salary Disbursement Accounts - HR/payroll accounts that credit many accounts regularly - Low counterparty diversity (same employees monthly) and high credit concentration superficially resemble mule structuring - Our `avg_credit_debit_ratio` feature partially addresses this

Informal Sector Accounts - Cash-heavy small traders with high `round_ratio` from legitimate cash transactions - Distinguishing feature: their `structuring_ratio` is low despite high `round_ratio` - Cash transactions cluster at truly round amounts (100, 500, 1000), not the sub-threshold structuring band (9,000–9,999)

9.2 False Negatives — Mules Missed by Our Model

The mule accounts our model consistently underscore share these characteristics:

Sophisticated Mules with Intentional Obfuscation

- Varying transaction amounts to avoid the structuring band

- Using many counterparties to raise diversity scores

- These accounts score 0.15–0.35 — above legitimate average but below our detection threshold

Short-Tenure Mules

- Accounts active for only 30-60 days with small transaction volumes

- Insufficient data to build reliable behavioral profile

- Our model requires a minimum transaction history to generate stable features

Mules Using Legitimate Business Covers

- Accounts registered as businesses that conduct genuine transactions alongside mule activity

- The genuine transactions dilute the behavioral signals

10. Final Results

10.1 Performance Summary

Metric	Public Score	Private Score	Context
AUC-ROC	0.9773	0.9671	Δ = -0.010: stable, minimal overfitting
F1 Score	0.5879	0.5090	Compressed probabilities limit F1 threshold sweep
Temporal IoU	0.6850	0.6181	743/960 true mule windows covered
RH_Avoidance_1	—	0.9904	High volume accounts: near-perfect
RH_Avoidance_2	—	0.9510	Seasonal spending: strong
RH_Avoidance_3	—	0.9040	Large transfers: strong
RH_Avoidance_4	—	0.9789	Dormant reactivation: strong
RH_Avoidance_5	—	0.9522	New account activity: strong
RH_Avoidance_6	—	0.9968	Branch clustering: near-perfect
RH_Avoidance_7	—	0.1429	Account takeover: acknowledged gap

10.2 Public → Private Stability

Our public AUC of 0.9773 dropped to private AUC of 0.9671 — a delta of **0.010**.

This is among the smallest public-to-private drops visible on the leaderboard, indicating our model **generalises well to the harder private test set with attenuated signals**.

Models with 0.999+ public AUC that drop significantly on private reflect overfitting to the public test distribution. Our modest drop indicates robust feature engineering and ensemble diversity.

11. Challenges Encountered & Solutions

Challenge 1: Class Imbalance (2.8% Mule Rate)

Problem: Standard classifiers produce degenerate models that predict all accounts as legitimate.

Solution:

- `scale_pos_weight=60` in XGBoost (above class ratio of 35)

- `class_weight='balanced'` in tree ensemble models

- Stratified train/val splitting preserving mule rate

Result: Achieved 0.9671 AUC with balanced precision/recall

Challenge 2: Temporal Window Localization

Problem: No labelled window data; ground truth windows may not align with statistically anomalous periods.

Solution:

- Evaluated burst detection, fixed windows, hybrid sizing

- Settled on wide window strategy (full transaction history span)

- Guarantees intersection coverage at cost of IoU precision

Result: IoU improved from 0.172 → 0.618 (+259%)

Challenge 3: Red Herring Accounts (RH_1–RH_7)

Problem: Legitimate accounts with anomalous patterns designed to mislead models.

Solution:

- Explicit feature engineering for each RH category

- Co-occurrence requirements (structuring + pass-through + diversity)

- Graph-based community detection for branch clustering

Result: RH Avg (1-6) = 0.9456; RH_7 = 0.1429 (acknowledged gap)

Challenge 4: Feature Compression & F1 Degradation

Problem: Ensemble probabilities compressed toward 0.5; F1 limited to 0.509.

Solution:

- Probability rescaling to [0.01, 0.99]

- Leaderboard threshold sweep finds optimal cutoff

- AUC unchanged (only ranking matters)

Result: F1 maintained at 0.509 despite probability spread

Challenge 5: RH_7 Account Takeover Detection

Problem: Account takeover patterns nearly identical to mule activation; distinguishing signals (device fingerprint, IP geolocation) unavailable.

Solution:

- Partial mitigation via `counterparty_diversity` (takeover victims transact with more diverse counterparties)

- Acknowledged gap; requires `transactions_additional` dataset integration

Result: RH_7 score = 0.1429 (honest assessment of limitation)

12. Conclusion & Future Work

12.1 Key Achievements

Our solution demonstrates that mule account detection benefits substantially from combining:

1. **Transaction behavioral features**: structuring patterns, pass-through ratios, flow anomalies

2. **Network graph analysis**: centrality measures, community detection, cycling scores

3. **Explicit red herring avoidance engineering**: targeted mitigations for 7 categories of legitimate accounts

The 4-model ensemble achieves **strong and stable discriminative performance** (AUC 0.9671) while maintaining **robustness across 6 of 7 red herring categories** (RH Avg 0.9456).

12.2 Directions for Future Improvement

Priority 1: RH_7 Avoidance (Account Takeover)

- Integrate device fingerprint and IP geolocation features from `transactions_additional` dataset

- Would allow explicit separation of account takeover from mule activation

- Expected improvement: RH_7 from 0.1429 → 0.85+

Priority 2: F1 Improvement via Probability Calibration

- Isotonic regression calibration on held-out validation set

- Would spread compressed probability distribution

- Expected improvement: F1 from 0.509 → 0.65+

Priority 3: Temporal Window Localization

- Accurately localising a 60-90 day suspicious window within a 5-year transaction history requires either: Supervised window labels, or Domain-informed prior on when mule operations typically occur relative to account opening

- Wide window strategy represents principled fallback guaranteeing intersection coverage

12.3 Regulatory Compliance

This solution directly operationalises: - **PMLA 2002** — identification of suspicious transactions and mule accounts - **RBI Cash Transaction Reporting Threshold** — structuring detection via ₹9,000–₹9,999 band - **FATF Guidance on Money Mules** — pass-through pattern detection - **RBI Cyber Fraud Circular 2023** — distinction between account takeover and deliberate mule recruitment

The solution is production-ready for deployment in Indian banking institutions subject to PMLA compliance.
